Abstract

Epithelioid glioblastoma is a new variant of glioblastoma that has been recently recognized in the 2016 WHO classification of brain tumors. Given the rarity of epithelioid glioblastoma, the clinical characteristics, pathological features, radiological findings, and treatment outcomes are still not well characterized. Therefore, we identified eighty-four epithelioid glioblastoma cases to investigate these characteristics and identify the possible prognostic factors of survival. There were 55 male and 29 female patients with a mean age of 33.6 years. Headache (77.3%) was the most common clinical symptom, and other common symptoms included nausea or vomiting (34%), dizziness (20.5%), seizures (13.6%), and limb weakness (13.6%). Most lesions (88.1%) were located in cerebral lobes, especially in the frontal lobe and temporal lobe. One hundred percent of the patients were IDH1 wild-type (75/75) and INI-1 positive (58/58), and 57.3% (47/82) of patients harbored BRAF^{V600E} mutation. The median overall survival (OS) of all patients was 10.5 months. Patients who received chemotherapy (p = 0.006) or radiotherapy (p = 0.022) had a longer survival than patients who did not. In addition, the K-M curve showed that the BRAF^{V600E} mutation status was not associated with survival (p = 0.724). These findings may assist clinicians with better understanding and management of epithelioid glioblastoma.

Keywords Epithelioid glioblastoma · Clinicopathological characteristics · BRAF^{V600E} mutation · Prognosis

Introduction

Glioblastoma is the most common primary malignant brain tumor and accounts for approximately 48% of primary malignant brain tumors [43], with a median survival of 14.6 months through current standard treatment of surgery plus concurrent chemoradiotherapy [36, 53]. Based on its morphological diversity and cellular heterogeneity, three uncommon variants of glioblastoma have been described, including giant cell glioblastoma, gliosarcoma, and epithelioid glioblastoma [31, 32]. Epithelioid glioblastoma is recognized as a new variant of glioblastoma and classified as a subtype of IDH wild-type glioblastoma in the 2016 World Health Organization (WHO) classification of brain tumors [32]. Histologically, it is characterized by monotonous, closely packed large epithelioid, melanoma-like cells with laterally positioned nuclei, prominent nucleoli, abundant eosinophilic cytoplasm, distinct cellular membranes, and lack of cytoplasmic stellate processes [1, 22, 32, 45]. Furthermore, BRAF^{V600E} mutation is found in nearly half of epithelioid glioblastomas, which is significantly higher when compared with conventional glioblastoma [3, 5, 23, 47]. Clinically, epithelioid glioblastoma tends to occur in young patients and often shows aggressive behaviors such as cerebrospinal fluid dissemination and extra-central nervous system (CNS) metastasis, which is different from conventional glioblastoma [5, 38].

It has been reported that epithelioid glioblastoma accounts for approximately 3% of all glioblastomas [44, 63]. Given the rarity of epithelioid glioblastoma, most of the published reports about epithelioid glioblastoma are either case reports or small case series so far [21, 26, 55, 63]. Previously, Lu et al. [33] searched the literature and performed an integrated survival analysis of epithelioid glioblastoma. However, the included cases in their study were confused between epithelioid glioblastoma and rhabdoid glioblastoma. Rhabdoid glioblastoma is another rare pattern of glioblastoma that has not been added into the WHO classification of brain tumors and can be distinguished from epithelioid glioblastoma by focal loss of

INI1 protein in rhabdoid areas and polyphenotypic immunohistochemical expression [22]. To date, the clinical characteristics, pathological features, radiological findings, and treatment outcomes of epithelioid glioblastoma are still not well characterized. Therefore, we conducted a systematic search of the literature about epithelioid glioblastoma to investigate these characteristics and identify the possible prognostic factors of survival.

Materials and methods

Case selection

We retrospectively reviewed glioma patients treated at the Department of Neurosurgery in West China Hospital between 2016 and 2019 and identified eight newly diagnosed epithelioid glioblastoma patients. We also systematically searched the literature published in English language about epithelioid glioblastoma from Web of Science and PubMed and ultimately identified seventy-six eligible cases with available clinical and survival data from twenty-four articles. The key terms used for search strategy were "epithelioid" and "glioblastoma." Meanwhile, the reference lists of included articles were also reviewed. The eligible cases met the following inclusion criteria: (1) the definite diagnosis of epithelioid glioblastoma was made; (2) the lesion was located in the brain; (3) basic clinical data and accurate survival data were available. When dealing with duplicated cases reported by the same author or institution, only the cases with more complete and updated data were selected. In addition, several reports using the terms "epithelioid glioblastoma" and "rhabdoid glioblastoma" interchangeably were excluded [2, 54]. This study was approved by the Ethics Committee of West China Hospital. Informed consent form for all included cases in our institution was obtained.

Data collection

Basic clinical data of our eight cases were extracted from our hospital information system and survival data were obtained from telephone interview. Data of reviewed cases were extracted from the texts, tables, and figures of the included articles. We recorded age, gender, clinical manifestation, radiological features, surgical treatment, adjuvant therapy, and survival data. In addition, available immunohistochemical staining results and molecular features such as P53 expression status, vimentin, epithelial membrane antigen (EMA), IDH1 mutation, INI1 loss, BRAF^{V600E} mutation, TERT promoter mutation, ATRX deletion, and MGMT promoter methylation were also collected.

Statistical analysis

SPSS software version 21.0 was used for data statistics and analysis. Continuous variables were presented as means and standard deviations or median and ranges, while categorical variables were presented as numbers and percentage. During data analysis, the median values of continuous variables were considered as cutoff values. Tumor diameter was divided into dichotomous variables. Age was divided into two groups: children group (< 18 years) and adult group (\geq 18 years). Survival analysis was performed twice with and without age stratification using Kaplan-Meier curves and tested by a logrank test. Two-tailed *p* value < 0.05 was considered statistically significant.

Results

Patient demographics and clinical characteristics

A total of 84 cases, including 76 cases identified from 24 articles and 8 cases from our institution, were included in this study. The details and summary of patient demographics and clinical characteristics are shown in Table 1 and Table 2. There were 55 male and 29 female patients, giving a maleto-female ratio of 1.9:1. The mean age was 33.6 ± 20.3 years and the median age was 30 years (range 2-79 years). Eighteen (21.4%) patients were children and 66 (78.6%) patients were adults. Seventy-eight patients were diagnosed with primary epithelioid glioblastomas, and six patients were diagnosed with secondary epithelioid glioblastoma. Of six secondary epithelioid glioblastomas, three cases were arising from pleomorphic xanthoastrocytoma, two cases were arising from anaplastic astrocytoma, and the other one was arising from grade III glioma (not available glioma type). Among 44 patients with available clinical symptoms, headache (77.3%) was the most common clinical symptom, and other common symptoms included nausea or vomiting (34%), dizziness (20.5%), seizures (13.6%), and limb weakness (13.6%).

In terms of tumor location, most lesions (88.1%) were located in cerebral lobes. The frontal lobe (39.3%) and temporal lobe (35.7%) were most often involved, followed by the parietal lobe (22.6%) and occipital lobe (10.7%). For lesions not located in cerebral lobes, four lesions were located in the thalamus, one in the hypothalamus, two in the lateral ventricle, one in the corpus callosum, and two in the cerebellum. In addition, the distribution of tumor was at the left side (43.5%), the right side (51.6%), midline (1.6%), and bilateral side (3.2%). The mean diameter of all available tumors was 4.6 ± 1.5 cm, with a median diameter of 4.7 cm (range 1.5–9.2 cm). In terms of surgical modalities for the patients with available surgical data, the majority of them (97.1%, 67/69) received surgical resection and two patients received only

biopsy. In addition, among 52 patients with available adjuvant treatment data, 35 (67.3%) patients received radiotherapy and 33 (63.5%) received chemotherapy.

Immunohistochemical results and molecular features

The summary of available immunohistochemical results and molecular features is shown in Table 3. One hundred percent of the patients were IDH1 wild-type (75/75) and INI-1 positive (58/58), whereas 7.3% (3/41) showed EGFR amplification and no one (0/26) showed 1p/19q deletion. Detection of $\mathsf{BRAF}^{\mathsf{V600E}}$ mutation was performed in 82 patients and 47 (57.3%) patients were mutant. P53 expression status was available in 66 patients and half of them were positive. MGMT promoter was methylated in 44.8% (13/29) of patients, TERT promotor mutation was detected in 52% (26/ 50) of patients, and ATRX loss was observed in 4.1% (2/49) of patients. CDKN2A/B deletion, PTEN deletion, and H3K27M mutation were found in 66.7% (14/21), 15.4% (4/26), and 2.7% (1/37) of patients, respectively. In addition, vimentin was positive in 97.6% (40/41) of patients and epithelial membrane antigen (EMA) was positive in 41.1% (23/ 56) of patients.

Survival outcome and prognosis analysis

The median overall survival (OS) of all patients was 10.5 months. In the survival analysis without age stratification shown in Table 4, there was no difference in survival between the genders (p = 0.967). The children group had a median OS of 12 months, and the adult group had a median OS of 9 months. However, the difference was not statistically significant (p = 0.156). Tumor location, tumor side, and tumor diameter were found to have no significant impact on OS. Patients who received chemotherapy (p = 0.006) or radiotherapy (p = 0.022) had a longer survival than patients who did not (Fig. 1). MGMT promoter methylation did not have an effect on patient survival (p = 0.606). In addition, the K-M curve showed that the BRAF^{V600E} mutation status was not associated with survival (p = 0.724). Also, results from the survival analysis using age stratification were consistent with those of unstratified analysis.

Discussion

Epithelioid glioblastoma is a rare subtype of IDH wild-type glioblastoma that has been recently recognized in the 2016 WHO classification of brain tumors [32]. It is noteworthy that epithelioid glioblastoma is distinguished from glioblastoma with epithelial metaplasia, which displays epithelial differentiation with squamous nests, glandular structures, and immunohistochemical expression of specific epithelial markers [45]. Histologically, epithelioid glioblastoma predominantly comprised discohesive sheets of epithelioid cells, and variably presents rhabdoid cells [1, 22, 32, 45]. The epithelioid cells are large round cells with laterally positioned nuclei, prominent

nucleoli, abundant eosinophilic cytoplasm, distinct cellular membranes, and lack of cytoplasmic stellate processes [1, 22, 32, 45]. Typical features of conventional glioblastoma, including necrosis, microvascular proliferation, and elevated mitotic activity, are also frequently seen [1, 21, 38, 63]. Unlike pleomorphic xanthoastrocytoma or other glioneuronal tumors, eosinophilic granular bodies and Rosenthal fibers are rarely seen in epithelioid glioblastoma [1, 14, 21, 22, 34].

It has been reported that epithelioid glioblastoma accounts for approximately 3% of all glioblastomas [44, 63]. Unlike conventional glioblastoma which is often diagnosed at older ages [43], this study showed that epithelioid glioblastoma tended to occur in children and young adults. The children group accounted for 21.4% of all included epithelioid glioblastomas, whereas the elderly group accounted for only 9.5%. The median age of all patients at diagnosis was 30

Table 4Survival analysis usinglog-rank test	Age stratification	Variable	n	χ2	p value
	All age group	Age, < 18/≥ 18 (years)	18/66	2.008	0.156

years, which is apparently younger than conventional glioblastoma with a median age of 65 years at diagnosis [43]. In addition, epithelioid glioblastoma had a predilection for males and the gender ratio of male-to-female was approximately 2:1. As far as clinical manifestations are concerned, there were no specific symptoms or signs. Headache was the most common clinical symptom, and other main symptoms included nausea or vomiting, dizziness, seizures, and limb weakness.

In terms of tumor location, epithelioid glioblastoma was mainly located in cerebral lobes, especially in the frontal lobe and temporal lobe. A few cases located in the thalamus [5, 63], hypothalamus [5], lateral ventricle [1, 39], cerebellum [14, 23], and spinal cord [1] also have been reported in the literature. There was a slight difference between left-sided and right-sided distribution, with a left-right ratio of 1:1.2. Radiologically, epithelioid glioblastoma often appeared as single superficially located, well-circumscribed, heterogeneously enhanced or ring enhanced mass [12, 18, 19, 22, 63]. Occasionally, it manifests as multifocal or multicentric lesions [15, 24]. More particularly, dura matter attachment, which is known to be common in meningioma, can sometimes be shown on enhanced magnetic resonance imaging of epithelioid glioblastoma [14, 18, 22, 63]. In such cases, epithelioid glioblastoma may be misdiagnosed as meningioma. As shown in Fig. 2 (illustrated case 81), MRI revealed a wellcircumscribed and markedly enhanced lesion with dura matter attachment in the left frontal lobe and it was initially diagnosed with meningioma.

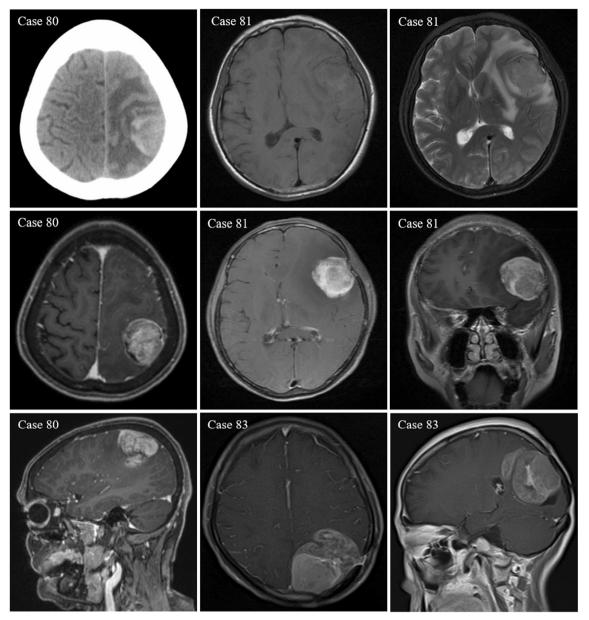

Fig. 2 Imaging characteristics of three illustrated cases from our institution. Epithelioid glioblastoma appeared as a superficially located, wellcircumscribed, and markedly enhanced mass with dura matter attachment on MRI images

Calcification, an important imaging characteristic of oligodendroglial tumors [52], can also be seen in epithelioid glioblastoma. In this study, five cases (cases 1, 2, 31, 55, and 56) showed calcification on CT scans. Interestingly, in case 31 and case 56, CT scans obtained 3 years before diagnosis showed abnormal areas with obvious calcification and CT scans performed at diagnosis showed the same calcification within the tumor. It suggested that abnormal areas may be the precursor lesions of epithelioid glioblastoma. In addition, the presence of coexisting lower grade glioma-like components with epithelioid glioblastoma has been reported in nine cases: diffuse astrocytoma-like components in six cases [26, 34, 38, 40], an anaplastic astrocytoma-like component in one case [38], an oligoastrocytoma-like component in one case [13], and an pleomorphic xanthoastrocytoma-like component in one case [38]. Furthermore, six out of 84 cases had a history of lower grade glioma in this study. Taking together, these findings suggested that epithelioid glioblastoma may develop from lower grade glioma through malignant transformation in some cases, and did not merely occur as primary or de novo lesions.

BRAF^{V600E} mutation, which can constitutively activate MAPK/ERK signaling pathway, has been detected in many different tumors, including approximately 60% of melanoma [9], 33% of papillary thyroid carcinoma [11], 12% of

colorectal cancer [10], and 2% of non-small cell lung carcinoma [7]. This mutation has also been found in several types of brain tumors, including pleomorphic xanthoastrocytomas (66%), gangliogliomas (18%), and pilocytic astrocytomas (9%), but rarely found in conventional glioblastoma (approximately 2%) [47]. Conversely, several studies suggested that nearly half of epithelioid glioblastomas harbored BRAF^{V600E} mutation [5, 23]. In this study, BRAF^{V600E} mutant epithelioid glioblastoma accounted for 57.3% of all cases. This finding suggested that BRAF^{V600E} mutation may serve as an auxiliary diagnostic biomarker for epithelioid glioblastoma. Moreover, one hundred percent of the cases were IDH1 wild-type and INI-1 was retained in all cases. Methylation of MGMT promoter was observed in 44.8% of cases and ATRX loss was observed in 4.1% of cases, which is similar to conventional glioblastoma [50, 56]. However, epithelioid glioblastoma showed a lower frequency of TERT promotor mutation (52%) and PTEN loss (15.4%) than conventional glioblastoma [50]. In addition, EGFR amplification was uncommon in epithelioid glioblastoma [1, 5, 21, 63], and only 7.3% of cases showed EGFR amplification in this study, which is significantly lower than in conventional glioblastoma (approximately 40%) [50]. Notably, no 1p/19q was found in any case of this study.

Epithelioid glioblastoma often showed aggressive behaviors such as cerebrospinal fluid dissemination and extra-CNS metastasis [1, 5, 38], which is distinctly different from conventional glioblastoma. The metastatic sites reported in the literature included the scalp, parotid gland, liver, lung, thoracic wall, lymph node, vertebral body, and peritoneum [5, 38, 40, 51]. Interestingly, two extra-CNS metastatic cases through a VP shunt were reported by Broniscer et al. [5], one was scalp metastasis and the other was peritoneal metastasis. Additionally, intratumoral hemorrhage, although relatively uncommon in glioma [41, 58], often occurred in epithelioid glioblastoma [5, 18]. In this study, nine cases (cases 1, 29, 30, 32, 41, 42, 56, 57, and 70) were described to have intratumoral hemorrhage. Several studies believed that discohesiveness of tumor cells and invasion into the vascular wall may be related to cerebrospinal fluid dissemination, extra-CNS metastasis, and intratumoral hemorrhage [26, 38].

Previous studies demonstrated that epithelioid glioblastoma had a particular poor prognosis [5, 38, 62]. This study showed that the median OS of epithelioid glioblastoma was 10.5 months, which is close to that reported by Wang et al. [59]. However, it is significantly shorter than that of conventional glioblastoma (14.6 months) [53]. It has been suggested that high-grade gliomas with leptomeningeal spread generally have a shorter survival [4]. Therefore, we speculated that such aggressive behaviors of epithelioid glioblastoma may be one cause of poor prognosis.

As is well known, surgery is the cornerstone in the initial treatment of glioblastoma [36, 60]. Many studies have

reported that the extent of resection in glioma surgery had an obvious effect on patient survival, and greater extent of resection was associated with improved overall survival [6, 17, 49]. In this study, the majority of the cases received surgical resection and two cases received only biopsy. Due to the limited cases with available data on extent of resection, extent of resection was not included in survival analysis, and more cases are needed to evaluate its effect on survival of epithelioid glioblastoma in the future. In addition, adjunct therapies including radiotherapy and chemotherapy have been demonstrated to be helpful for prolonged survival of glioblastoma [53]. Likewise, this study showed that both radiotherapy and chemotherapy were significantly associated with improved overall survival. These results indicated that epithelioid glioblastoma also benefited from standard chemotherapy and radiotherapy for conventional glioblastoma. Moreover, an interesting case of BRAF wild-type epithelioid glioblastoma going through complete regression on imaging after radiotherapy plus chemotherapy has been recently reported [61]. Regrettably, only 67.3% of patients received radiotherapy and 63.5% of patients received chemotherapy in this study. Based on available information, case 44 refused chemotherapy for unknown reason and sought nutritional therapy. Case 60 was complicated by steroid-induced psychosis and incapable of receiving radiotherapy. Case 77 refused radiotherapy and chemotherapy due to poor economic conditions and case 81 was afraid of side effects of radiotherapy. Such reasons tell us that enhancing patients' understanding of the disease and chemoradiotherapy may help to increase the proportion of patients receiving chemoradiotherapy and thus improve prognosis.

MGMT promoter methylation status has emerged as an important prognostic factor in glioblastoma [16, 42]. It is known that MGMT methylation is associated with better prognosis and better response to temozolomide [16, 42]. However, MGMT methylation was found to have no significant impact on OS in this study. Given the small number of cases analyzed, future studies with a large number of cases are still needed to evaluate its effect on prognosis of epithelioid glioblastoma. BRAF^{V600E} mutation has been reported to be associated with poor prognosis in some tumors, including papillary thyroid carcinoma, melanoma, and colorectal cancer [30, 46]. Given the high BRAF^{V600E} mutation rate and poor prognosis of epithelioid glioblastoma, we doubted whether $BRAF^{V600\vec{E}}$ mutation was a bad biomarker for overall survival. Therefore, BRAF^{V600E} mutation was included in the survival analysis and it showed no difference in survival between wildtype and mutant BRAF^{V600E} epithelioid glioblastoma. Previously, one study indicated that $BRAF^{V\bar{6}00E}$ mutation was related to poor prognosis in pediatric low-grade gliomas [27], while another study by Zhang et al. [64] demonstrated that this mutation was a favorable prognostic factor in young adult glioblastoma patients. At present, the prognostic value of $BRAF^{V600E}$ mutation in glioma remains controversial and more studies are needed to investigate its prognostic impact on glioma.

Limitations

This study has several limitations. Firstly, this study was a retrospective analysis and most cases were reviewed from published case reports and case series, which could lead to selection or publication bias. Secondly, the sample size was relatively small, which results in low statistical power and may limit the universality of these findings. Thirdly, immunohistochemical results may be unconvincing due to lack of unified standards. In addition, subgroup analysis stratified by extent of resection and Karnofsky performance status was unable to be performed due to limited cases with available related data.

Conclusions

Epithelioid glioblastoma is a rare subtype of IDH wild-type glioblastoma. In this study, we summarized clinical characteristics, imaging findings, histopathological features, and genetic alterations of epithelioid glioblastoma and identified the prognostic factors of survival. These findings may assist clinicians with better understanding and management of epithelioid glioblastoma.
